# bisection method

Calculates the root of a univariate function using the bisection method.

#### **Syntax**

```
root = bisection_method(f,a,b)
root = bisection_method(f,a,b,TOL)
root = bisection_method(f,a,b,[],imax)
root = bisection_method(f,a,b,TOL,imax)
root = bisection_method( ,'all')
```

#### **Description**

root = bisection\_method(f,a,b) returns the root of a function f(x) specified by the function handle f, where a and b define the initial guess for the interval [a,b] containing the root. The default tolerance and maximum number of iterations are TOL = 1e-12 and imax = 1e6, respectively.

root = bisection\_method(f,a,b,TOL) returns the root of a function f(x) specified by the function handle f, where a and b define the initial guess for the interval [a,b] containing the root and TOL is the tolerance. The default maximum number of iterations is imax = 1e6.

root = bisection\_method(f,a,b,[],imax) returns the root of a function f(x) specified by the function handle f, where a and b define the initial guess for the interval [a,b] containing the root and imax is the maximum number of iterations. The default tolerance is TOL = 1e-12.

root = bisection\_method(f,a,b,TOL,imax) returns the root of a function f(x) specified by the function handle f, where a and b define the initial guess for the interval [a,b] containing the root, TOL is the tolerance, and imax is the maximum number of iterations.

root = bisection\_method(\_\_\_,'all') returns a vector, where the first element of this vector is the initial guess, all intermediate elements are the intermediate estimates of the root, and the last element is the converged root. This identifier 'all' may be appended to any of the syntaxes used above.

#### **Examples**

Example 1

Find the root(s) of  $f(x) = x^2 - 1$ .

#### **■** SOLUTION

```
Defining f(x),

f = e(x) x^2-1;
```

We know  $f(x) = x^2 - 1$  has roots at  $x = \pm 1$ , but let's pretend we don't know this, and solve this problem

using a more general approach. Since f(x) is a quadratic function, we know that it will have either 0 roots (in the case where f(x) does not cross the x-axis) or 2 roots. Let's assume the latter case (otherwise it would be pointless to try and find roots of f(x)). Therefore, we use the bisection method twice, with two different guesses for the interval containing the root. Let's pick [-10,0] and [0,10] as our initial guesses for this interval.

Example 2

Find a root of g(x) = h(m(x)), where  $h(x) = 5x^2 - 4$  and  $m(x) = \cosh \sqrt{x}$ . Additionally, plot the intermediate root estimates vs. iteration number.

#### **■** SOLUTION

First, let's define g(x). Instead of defining it as an anonymous function, we define it as a regular MATLAB function (note that we must either put this function in a separate  $\cdot m$  file or place it at the end of the script).

```
function g = gx(x)
    m = cosh(sqrt(x));
    h = 5*m^2-4;
    g = h;
end
```

However, we cannot use gx directly with bisection\_method. Instead, we first have to assign a function handle to gx (this allows us to pass the function to another function as an input parameter).

```
g = \theta(x) gx(x);
```

Due to the complexity of g(x), we have no idea where its root(s) is/are<sup>a</sup>. Let's make the initial guess [a, b] = [-5, 5]. Solving for the root with the bisection method,

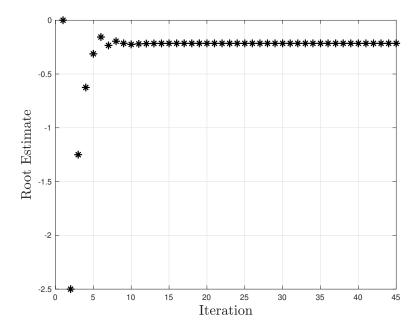

```
root = bisection_method(g,-5,5)
This yields the result
```

root =

-0.2150

To plot the root estimates vs. iteration number,

#### This yields the following plot:

 $<sup>\</sup>overline{a}$  In fact, it has multiple roots. Here, we only solve for one.

## **Bisection Method**

The **bisection method** can be used to find the root of a univariate function f(x), with no restrictions on the differentiability of f. The basic idea behind the bisection is starting off with some interval [a,b] containing a root, iteratively "shrinking" this interval until it is below some tolerance threshold, and then taking the root to be the midpoint of this interval. The general procedure is as follows:

- 1. Make an initial guess for the interval [a, b] containing the root.
- 2. Assume the root, c, is the midpoint of this interval: c = (a + b)/2.
- 3. Evaluate f(a) and f(c).
  - (a) If f(a) < 0 and f(c) > 0 (i.e. they have different sign), we know the true root is contained in the interval [a, c]. Therefore, we update our interval so that a remains the same, but b is updated to be c.
  - (b) If f(a) and f(c) have the same sign (either both negative or both positive), we know the true root must be contained in the interval [c, b]. Therefore, we update our interval so that b remains the same, but a is updated to be c.
- 4. Repeating steps 2 and 3, the interval [a,b] will keep shrinking. Once the difference (b-a) is small enough, we say that the estimate of the root has **converged** to the true root, within some **tolerance** (which we denote as TOL). Therefore, if we predetermine that, at most, the root must be restricted to an interval of length TOL, we will keep repeating steps 2 and 3 until (b-a) < TOL.

In some cases, the difference (b-a) may never decrease below TOL, or take too long to decrease to below TOL. Therefore, we also define the **maximum number of iterations**  $(i_{max})$  so that the algorithm does not keep iterating forever, or for too long of a time [1, 2].

There are two basic algorithms for implementing the bisection method. The first implementation, shown in Algorithm 1 below, does *not* store the result of each iteration. On the other hand, the second implementation, shown in Algorithm 2, *does* store the result of each iteration. bisection method implements both of these algorithms.

Since Algorithm 2 first needs to preallocate a potentially huge array to store all of the intermediate solutions, Algorithm 1 is significantly faster. Even if  $i_{\text{max}}$  (determines size of the preallocated array) is set to be a small number (for example, 10), Algorithm 1 is still faster. The reason we still consider and implement Algorithm 2 is so that convergence studies may be performed.

#### **Algorithm 1:** Bisection method.

```
1 Given: f(x), a, b, TOL, i_{max}
  // sets initial guess
\mathbf{2} \ c = \frac{a+b}{2}
  // bisection method
i = 1
4 while (b-a) > \mathrm{TOL} and i < i_{\mathrm{max}} do
       // updates interval
       if f(c) = 0 then
5
6
       Stop
       else if sgn[f(c)] = sgn[f(a)] then
        a = c
8
       else
9
       b=c
10
       end
11
       // updates root estimate
12
       // increments loop index
       i = i + 1
13
14 end
   // returns root
15 root = c
```

16 return root

#### Algorithm 2: Bisection method with intermediate root estimates.

- 1 Given: f(x), a, b, TOL,  $i_{max}$
- 2 Preallocate an  $i_{\rm max} \times 1$  vector x, where x is the vector storing the estimates of the

```
root at each iteration.
   // inputs initial guess for root into x vector
x_1 = \frac{a+b}{2}
   // bisection method
 4 i = 1
 5 while arepsilon > \mathrm{TOL} and i < i_{\mathrm{max}} do
       // updates interval
       if f(x_i) = 0 then
 6
          Stop
 7
       else if sgn[f(x_i)] = sgn[f(a)] then
 8
           a = x_i
 9
       else
10
        b=x_i
11
       end
12
       // updates root estimate
       x_{i+1} = \frac{a+b}{2}
13
       // increments loop index
       i = i + 1
14
15 end
   // stores intermediate root estimates (where last element of root is the converged root)
16 root = (x_1, ..., x_i)^T
   // returns root
17 return root
```
