1   BISECTION METHOD

The **bisection method** can be used to find the root of a univariate function $f(x)$, with no restrictions on the differentiability of f. The basic idea behind the bisection is starting off with some interval $[a, b]$ containing a root, iteratively "shrinking" this interval until it is below some tolerance threshold, and then taking the root to be the midpoint of this interval. The general procedure is as follows:

1. Make an initial guess for the interval $[a, b]$ containing the root.
2. Assume the root, c, is the midpoint of this interval: $c = (a + b)/2$.
3. Evaluate $f(a)$ and $f(c)$.
   (a) If $f(a) < 0$ and $f(c) > 0$ (i.e. they have different sign), we know the true root is contained in the interval $[a, c]$. Therefore, we update our interval so that a remains the same, but b is updated to be c.
   (b) If $f(a)$ and $f(c)$ have the same sign (either both negative or both positive), we know the true root must be contained in the interval $[c, b]$. Therefore, we update our interval so that b remains the same, but a is updated to be c.
4. Repeating steps 2 and 3, the interval $[a, b]$ will keep shrinking. Once the difference $(b - a)$ is small enough, we say that the estimate of the root has **converged** to the true root, within some **tolerance** (which we denote as TOL). Therefore, if we predetermine that, at most, the root must be restricted to an interval of length TOL, we will keep repeating steps 2 and 3 until $(b - a) < \text{TOL}$.

In some cases, the difference $(b - a)$ may never decrease below TOL, or take too long to decrease to below TOL. Therefore, we also define the **maximum number of iterations** ($i_{\max}$) so that the algorithm does not keep iterating forever, or for too long of a time [1, 2].

     There are two basic algorithms for implementing the bisection method. The first implementation, shown in Algorithm 1 below, does *not* store the result of each iteration. On the other hand, the second implementation, shown in Algorithm 2, *does* store the result of each iteration. `bisection_method` implements both of these algorithms.

     Since Algorithm 2 first needs to preallocate a potentially huge array to store all of the intermediate solutions, Algorithm 1 is significantly faster. Even if $i_{\max}$ (determines size of the preallocated array) is set to be a small number (for example, 10), Algorithm 1 is still faster. The reason we still consider and implement Algorithm 2 is so that convergence studies may be performed.

Algorithm 1:

Bisection method (fast implementation).

Given:
- $f(x)$ - function
- a - lower bound for initial guess of interval with root
- b - upper bound for initial guess of interval with root
- TOL   - tolerance
- $i_{\max}$ - maximum number of iterations

Procedure:
1. Initial guess for root.

$$c = \frac{a + b}{2}$$

2. Initialize x_{new} so its scope will not be limited to within the while loop.

$$x_{\text{new}} = 0$$

3. Initialize the loop index.

$$i = 1$$

4. Find the root using the bisection method.

> **while** $((b - a) > \text{TOL})$ **and** $(i < i_{\max})$
>
> > (a) Update interval.
> >
> > > **if** $f(c) = 0$
> > > > **Stop**
> > > **else if** $\text{sgn}\,[f(c)] = \text{sgn}\,[f(a)]$
> > > > $a = c$
> > > **else**
> > > > $b = c$
> > > **end**
> >
> > (b) Update root estimate.
> >
> > $$c = \frac{a + b}{2}$$
> >
> > (c) Increment loop index.
> >
> > $$i = i + 1$$
>
> **end**

Return:
- $\text{root} = c$ - converged root

Algorithm 2:
Bisection method (storing intermediate root estimates).

Given:
- $f(x)$ - function
- a - lower bound for initial guess of interval with root
- b - upper bound for initial guess of interval with root
- TOL   - tolerance
- $i_{\max}$ - maximum number of iterations

Procedure:
1. Preallocate $\mathbf{x} \in \mathbb{R}^{i_{\max}}$ to store the estimates of the root at each iteration.
2. Store the initial guess for the root in the first element of $\mathbf{x}$.

$$x_1 = \frac{a + b}{2}$$

3. Initialize the loop index.

$$i = 1$$

4. Find the root using the bisection method.

> **while** $((b - a) > \text{TOL})$ **and** $(i < i_{\max})$

(a) Update interval.

$$\begin{aligned}
&\textbf{if } f(x_i) = 0 \\
&\quad\quad \textbf{Stop} \\
&\textbf{else if } \mathrm{sgn}\,[f(x_i)] = \mathrm{sgn}\,[f(a)] \\
&\quad\quad a = x_i \\
&\textbf{else} \\
&\quad\quad b = x_i \\
&\textbf{end}
\end{aligned}$$

(b) Update root estimate.

$$x_{i+1} = \frac{a+b}{2}$$

(c) Increment loop index.

$$i = i + 1$$

end

Return:

- **x**   - vector where the first element is the initial guess for the root, the subsequent elements are the intermediate root estimates, and the final element is the converged root
